Liver Transplantation for Cardiac Failure in Patients With Hereditary Hemorrhagic Telangiectasia

Thierry Thevenot,1 Claire Vanlemmens,1 Vincent Di Martino,1 Marie-Claude Becker,1 Pierre-Olivier Denue,2 Bernadette Kantelip,3 Solange Bresson-Hadni,1 Bruno Heyd,2 Georges Mantion,2 and Jean-Philippe Miguet1

Liver involvement in hereditary hemorrhagic telangiectasia may lead to high-output cardiac failure. Few data have been reported on orthotopic liver transplantation (OLT) for these patients. In this paper, we describe two patients treated by OLT as a salvage procedure for cardiac failure, and we review literature on this subject. Our two patients resumed normal cardiac function after OLT. This procedure appears to be a promising therapy with good long-term results despite dissection difficulties encountered due to the collateral arterial network reorganization. (Liver Transpl 2005;11:834-838.)

Hereditary hemorrhagic telangiectasia (HHT), also known as Osler-Rendu-Weber disease, is a systemic fibrovascular dysplasia with a dominant inherited autosomal pattern that is caused by the mutation of two genes: ENG and ALK1. The estimated prevalence of HHT varies greatly but is higher in some regions of France (1 per 10,000 individuals).1 The typical manifestations are mucocutaneous or visceral angiodysplastic lesions (telangiectasias and arteriovenous malformations) including the lungs, gastrointestinal tract, brain, and liver. Hepatic involvement is observed in 8% to 31% of patients,2,3 but a high percentage of patients are asymptomatic.4,5 The main clinical presentation in patients with liver involvement has been cardiac failure and orthotopic liver transplantation (OLT) appears to be a promising therapy. Few cases of OLT for high-output heart failure have been reported to date.6-12

Herein we describe two patients with cardiac failure for whom OLT was successful but included thrombotic complications in the follow-up.

Case 1

In December 2000, a 59-year-old woman developed anorexia, a 10-kg weight loss over a 2-month period, progressive dyspnea, and encephalopathy. She had a neglected history of nosebleeds, and one of her two sons had iterative epistaxis. Physical examination revealed fever, jaundice, cardiac failure with dilated jugular veins, bilateral pleural effusion, peripheral edema, and telangiectasias on the patient’s cheeks, lips, and back. Laboratory data disclosed a neutrophil count of 36,000/mm³, C-reactive protein 66 mg/L and an icteric cholestasis. Echocardiography noted a dilated right ventricular and a small pericardial effusion. An abdominal computed tomography scan showed an 8-cm diameter intrahepatic biloma (Fig. 1A), confirmed by puncture. Visceral angiography showed a bilateral diffusely hypervascular liver parenchyma in the capillary phase with early prominent hepatic venous filling (Fig. 1B); a selective superior mesenteric artery injection indicated shunting of blood away from the mesenteric circuit through the pancreaticoduodenal arcades and into the liver. Gastroscopy revealed two antral telangiectasias but no portal hypertension sign. Right heart catheterization showed cardiac output at 8.4 L/min and cardiac index at 5.09 L/min/m². An elective arterial embolization of the left hepatic artery was performed to decrease the intrahepatic arteriovenous shunting. Although the heart failure improved, hepatobiliary necrosis of segments II and III developed with deterioration of the liver function (factor V level 46%) consecutive to the persistence of the sepsis. The patient underwent OLT in February 2001 as treatment for biliary sepsis and cardiac failure. The dissection was difficult with a spontaneous splenic rupture when the portal vein was clamped, first requiring a temporary portocaval shunt and thereafter an urgent splenectomy. Transfusion of 25 blood units was necessary and the duration of cold ischemia was 8.5 hours. Four months
later, the patient developed celiac artery thrombosis with no evidence of thrombophilia, followed by resumed permeability under fluindione. ALK1 mutation was found 1 year later, and the diagnosis of HHT type 2 with liver involvement was definitively ascertained. Three years later the patient is now in good health with a total recovery of cardiac function.

Case 2

In September 2002, a 62-year-old woman complaining of progressive breathing difficulties was admitted to the cardiology unit of Besançon Hospital. HHT had been diagnosed 30 years previously because of recurrent epistaxis and a family history of nosebleeds. The patient had arterial hypertension, Fernand Widal syndrome, and had undergone a resection of an aneurysm of the pancreatico-duodenal arcade in 1985. On admission, multiple telangiectasias on the tongue and fingers, and edema of the lower limbs were present. Laboratory data showed anicteric cholestasis (alkaline phosphatase 2.7 N and gammaglutamyl transpeptidase 6 N) with a normal prothrombin time. Color Doppler sonography indicated a high-velocity signal in an enlarged hepatic artery. Gastroscopy showed mucosal telangiectasia in the stomach. An echocardiography revealed severe tricuspid regurgitation, a right dilated cavity with a dilated inferior cava vein. Right heart catheterization showed cardiac output at 10.7 L/min and cardiac index at 6.56 L/min/m². The patient underwent OLT in October 2002 because of high-output heart failure. The mean operation time was 6.5 hours, and 5 blood units were transfused. The result of ALK1 mutation confirmed the diagnosis of HHT type 2. In November 2003 the patient was readmitted because of acute abdominal pain with moderate ascites. Doppler ultrasound detected a mesenteric and splenic vein thrombosis extending to the distal part of the portal trunk without portal cavernoma, suggesting recent portal thrombosis. An investigation was carried out for acquired and inherited thrombophilia (protein C, protein S, antithrombin III deficiencies, factor V Leiden and factor II mutation, antiphospholipid antibodies, homocysteinemia, paroxysmal nocturnal hemoglobinuria) and for local factors (abdominal computed tomography), but all of these exams were noncontributive. Also, bone marrow examination did not demonstrate overt or latent myeloproliferative disorders. A prompt anticoagulation therapy was started and has been continued. In October 2004 recanalization of portal, mesenteric, and splenic vein was reestablished on color Doppler ultrasound. Likewise, two years after OLT cardiac function and echocardiography returned to normal.

Discussion

HHT remains a clinical diagnosis based on the Curaco criteria requiring at least two of the following extrahepatic manifestations: epistaxis, cutaneomucosal telangiectasia, and a family history of HHT. HHT is now more easily confirmed thanks to the recent discovery of two major genes, ENG and ALK-1, which define two disease types with different phenotypic patterns: HHT1 associated with pulmonary arteriovenous malformations, and HHT2 with high incidence of liver involvement.

Hepatobiliary manifestations of HHT may be clinically brought to light by the appearance of encephalopathy due to porto-venous shunts, portal hypertension with variceal bleeding, or ascites due to arterio-portal shunts, and recurrent cholangitis or hemobilia. However, the most important symptoms of HHT with liver involvement are related to cardiac failure caused by left-to-right arterio-venous shunts, as in our two cases. Cardiovascular symptoms occur when intrahepatic shunt output is more than 20% of cardiac output. Cardiac output is almost always increased in these patients in up to 21.3 L/min, and the shunt output has been reported as high as 68% of cardiac output. Among the 19 patients of the Garcia-Tsao et al. series...

* This malformation was symptomatic 10 years after OLT.
having HHT with liver involvement, only 1 patient had a normal cardiac index.\textsuperscript{3} Cardiac failure during pregnancy has also been well described, always resulting in premature delivery, due mainly to a 30% to 40% increase in blood volume at the end of gestation combined with the increasing number and size of shunting.\textsuperscript{5,6,17,21,22} The diagnosis can be approached by angiography showing a typically dilated hepatic artery, small vascular lesions scattered in the liver, and early filling of the hepatic vein due to arteriovenous shunting.

Several radiological and surgical therapies attempt to achieve a reduction in cardiovascular symptoms. Embolization, calibration, or ligature of the hepatic artery to reduce the high cardiac output are only successful in the short term because of the development of new arteriovenous hepatic malformations. Furthermore, these invasive procedures performed on the hepatic artery may lead to ischemic cholangitis occurrence because biliary tree vascularization depends mainly on hepatic artery flow.\textsuperscript{7} For all these reasons, OLT is now considered to be a promising treatment for HHT with liver involvement because it restores cardiac function and normalizes arterial and venous hepatic blood flow. To date, only 24 liver transplantations performed for HHT have been reported.\textsuperscript{6,12,23-26} According to the Garcia-Tsao et al. classification, the predominant clinical presentation was cardiac failure in 13 cases (Table 1),\textsuperscript{6-12} biliary disease in 7 cases,\textsuperscript{8,17,23,25} portal hypertension in 3 cases,\textsuperscript{8,24} and not specified in 1 patient receiving a right hemiliver from a living donor.\textsuperscript{26}

The results of OLT are considered to be good despite dissection difficulties due to vascular reorganization.\textsuperscript{6,8,24} In the Paul Brousse hospital experience, OLT required transfusion of 16 to 88 blood units, and the mean operation time varied from 11 to 15 hours for the 6 cases reported.\textsuperscript{8} Of the 24 OLTs currently reported, only 2 patients who underwent transplantation died postoperatively at 7 and 11 days due, respectively, to massive pulmonary and gastric bleeding resulting from the rupture of an arteriovenous malformation. However, a closer screening of the patient with a silent pulmonary arteriovenous malformation should be performed and the malformation detected and treated before the patient receives a right hemiliver from a living donor.\textsuperscript{26} The hemodynamic parameters and right-heart diameters improved or normalized in all living patients (Table 1). Recently, Sabbà et al. highlighted the possibility of reappearance of arteriovenous malformations despite OLTs performed 8 and 10 years earlier in two patients.\textsuperscript{10} However, in the second case, the focal vascular dilatation was asymptomatic and could have been due to peliosis hepatitis, a well-known condition encountered in patients who have undergone transplantation. Close monitoring of these patients, even several years after OLT, should be performed.

Finally, we consider that OLT for HHT with liver involvement is currently the most promising therapy with good long-term results, allowing normalization of the cardiac function. However, liver transplantation for HHT remains a difficult procedure due to the collateral arterial reorganization. Moreover, the occurrence of thrombotic complications in our two cases is intriguing. OLT should probably be considered earlier in the therapeutic strategy before the appearance of a fixed secondary pulmonary hypertension. The various instrumental techniques performed on the hepatic artery should only be recommended as a temporary bridge to bringing the patient to OLT and should be closely monitored, especially in the case of previously altered liver function.

Acknowledgments

We thank Dr. Florence Fellmann from the Department of Genetics, CHU Besançon, who performed the genetic diagnosis of HHT in our two patients.
